Title: Improving **Data-Driven Flow Forecasting in Large Basins using Machine** Learning to Route Flows

AUTHORS:

Mostafa Elkurdy, Laura Read, Alden Keefe Sampson, Phil Butcher, Marshall Moutenot

BACKGROUND: Making accurate hourly

streamflow forecasts in large and regulated basins is difficult without a distributed model to divide the input data and routing so that peak magnitudes and timing are well captured.

Learn how we have incorporated a distributed model into HydroForecast's short-term model.

METHODS

- **1.** Start with HydroForecast core [*a theory-guided* machine learning model]
- 2. Delineate subbasins, split at upstream gauges

- **3.** Predict runoff at each HRU
- **4.** Route runoff through the river network. For each layer:
- Add up inflows to each confluence in layer
- Flow (delay) water down each reach in a layer

The distributed model efficiently routes flows by first determining upstream dependencies. Forecasts are produced for the upstream most subbasins (represented by the *lightest* colors) in parallel and added to the next layer of directly downstream subbasins. This allows the model to compute total flows at every point in the least amount of time while minimizing computational demand.

First operational, deep learning, hydrologic forecasting model that learns routing and hydrology at once

Monthly average snow cover, 2019.

Example, Christmas 2020 rain on snow event in White River, CT

What's especially unique and new

The model predicts **three** components dynamically at every time step for every reach: the delay time, spread and volume gain/loss.

The model learns the dynamic routing properties

We use matrix multiplication to make this speedy fast. Run time for total **flow predictions** on a GPU:

• ~50,000 km² in ~**2 seconds** • ~5,000 km² in ~ < **1 second**

Assimilation: Impact of incorporating upstream forecasts
